(Dated: January 19, 2013)

A Keldysh-contour effective field theory is derived for magnetic vortices in the presence of current flow. The effect of adiabatic and non-adiabatic spin transfer torques on vortex motion is highlighted. Similarities to and differences from the superconducting case are presented and explained. Current flow across a magnetically ordered state is shown to lead to a defect-unbinding phase transition which is intrinsically nonequilibrium in the sense of not being driven by a variation in effective temperature. The dependence of the density of vortices on the current density is determined.

I. INTRODUCTION

The nonequilibrium physics of strongly interacting quantum systems is a topic of fundamental theoretical importance. A question of particular current interest is the behavior of quantum critical systems under nonequilibrium conditions. Examples include phase transitions induced at temperature $T=0$ in the presence of a nonequilibrium drive¹⁻⁶ as well as quantum coarsening and quench problems of a system prepared or maintained in a far-from equilibrium state.⁷⁻¹¹ In many of the cases of nonequilibrium quantum criticality studied to date, the dominant physics is that the nonequilibrium drive acts to produce a noise term (typically delta-correlated at long scales) in the equation of motion for the critical fluctuations.¹ This noise term increases fluctuations and destroys order, similarly to temperature. Differences from equilibrium physics of course appear, for example as violations of the fluctuation-dissipation theorem^{8,12} or as subleading corrections to scaling.^{5,13} Other situations can occur too. For example, Dalle Torre *et al* showed that in some circumstances departure from equilibrium can lead to a noise with long ranged correlations, which leads to larger differences from equilibrium physics.⁶ In some models, excitations propagate ballistically so the concept of effective temperature does not apply and nonequilibrium phase transitions arise for different reasons.^{2,9,14}

In this paper we investigate an alternative route to nonequilibrium quantum criticality. We show that in continuous-symmetry magnets an applied current can lead to a current-driven defect unbinding. This has no equilibrium analogue and therefore constitutes an intrinsically nonequilibrium phase transition, quantum in the sense that it is driven at $T=0$. Of course, even at $T=0$ a driving field will introduce a noise, but analogously to the nonequilibrium classical phase transitions occurring e.g. in sheared liquids,¹⁵ the noise is not the crucial parameter. The mechanism we discuss is generic, applying (with some difference of details) for any combination of dimensionality and order parameter symmetry for which topological defects can be defined. For definiteness we present specific results in the case of a quasi two-

dimensional XY magnet, for which the defects involved are vortices. In this respect our work complements the treatment of current-driven quantum criticality in our previous papers^{1,13} which treated Ising and Heisenberg symmetries and found that the transition was driven by a current-induced noise.

That an applied current can lead to a force on a magnetic defect was previously known.¹⁶⁻¹⁸ The transition we find is analogous to defect-unbinding transitions driven by supercurrent flow in superfluids.^{19,20} The new contributions of this paper include a derivation from microscopics which is somewhat different from (although basically in agreement with) previous work,²¹⁻²⁵ a discussion of the mapping between the superconducting and magnetic situations, some additional insights into the relative importance of the different mechanisms by which Galilean invariance is broken and explicit results for the defect creation rates.

Our approach is to write a general interacting fermion model in the presence of a nonequilibrium drive as a Keldysh-contour path integral, introduce magnetic degrees of freedom via a Hubbard-Stratonovich transformation of the fermion-fermion interactions and by integrating out the fermions obtain a nonequilibrium spin model. We use a method presented by Schulz²⁶ to introduce rotational degrees of freedom and use an expansion in gradients and quantum fluctuations to obtain an action in terms of rotational spin excitations. The mean field approximation to this action is the Landau-Lifshitz-Gilbert equations. By representing magnetic configurations in terms of topological (vortex) coordinates¹⁸ we obtain an action for the topological excitations, which is then analyzed via quantum critical and instanton methods.

The rest of this paper is organized as follows. Section II outlines the approach we use, Sections III and IV present a derivation of the basic dynamical effects, Section V summarizes the resulting action in spin coordinates, Section VI derives the action for topological defects, Section VII describes the current-driven vortex unbinding transition and Section VIII is a summary and conclusion.

II. FORMALISM

A. Overview

We are interested in the effect of current drive on the nucleation and motion of topological defects in the magnetization field of a metallic ferromagnet. Although our formalism can be applied to the case of any topological defect, we present explicit results for vortices: the topological defects in a two dimensional easy-plane magnet. Because topological defects are large scale structures in the spin field, they obey equations of motion which may be deduced from semiclassical arguments based on the Landau-Lifshitz-Gilbert equation.^{16,17,22} Denoting the position of defect i by \vec{X}_i and the sign of its vorticity by $\eta = \pm 1$, we may represent its equation of motion as

$$\eta \mathcal{C} \mathcal{J}_0 \hat{z} \times \dot{\vec{X}}_i + I_D \mathcal{D}_0 \dot{\vec{X}}_i = \eta \mathcal{C} \hat{z} \times \vec{\mathcal{J}} + I_D \vec{\mathcal{D}} + \sum_j \vec{F}_{ij} + \vec{\zeta}_i \quad (1)$$

with \vec{F}_{ij} the force due to the intervortex interaction (including both spin-wave-mediated and dipolar terms). The terms $\vec{\mathcal{J}}$ and $\vec{\mathcal{D}}$ arise due to current flow, while \mathcal{J}_0 and \mathcal{D}_0 representing the effects of spin conserving and non-conserving processes on the temporal dynamics. I_D and \mathcal{C} are constants and ζ_i is a fluctuating field which on scales longer than the mean free path may be taken to be delta correlated, with

$$\langle \zeta_i^a(t) \zeta_j^b(t') \rangle = 2I_D N^{xx} T^* \delta_{ij} \delta^{ab} \delta(t - t') \quad (2)$$

Here N^{xx} is related to the many-body density of states and T^* is an effective temperature arising from the departures from equilibrium.

In this paper we employ a Keldysh-contour based nonequilibrium approach to calculate the coefficients in Eq. (1) in terms of the underlying properties of the electrons (in particular the transport and spin relaxation times) and the applied current, determining the relative magnitudes of the different terms and explicating the similarities and differences between topological defects in superconductors and in magnets.

The formalism is based on a phase angle representation convenient for carrying out a gradient expansion. It enables a quantitative understanding of the origin of the breaking of Galilean invariance, of the roles of spin conserving and non-conserving scattering mechanisms, and of the variations of parameters as the magnetic critical point is approached. We show that in the generic situation when the spin non-conserving scattering is small compared to the spin conserving scattering, then the vortex Hall angle is typically near to 90° (in contrast to the result for superconductors), but the drag contribution to the force on a vortex is much larger than the transverse ('Magnus') force contribution (also different from the usual case of vortices in superconductors). These results, in combination with the effects of the long-ranged

dipole interaction, lead to quantitative differences in the current-induced nucleation of vortices.

B. Basic Assumptions

We consider a system of interacting fermions and make the Fermi liquid assumption that the dynamical effects of the electron-electron interaction may be neglected at the scales of interest here. The system is then characterized by a band structure, which we represent via a hopping matrix t_{i-j} connecting unit cells i and j , and a local magnetization

$$\vec{m}(\vec{r}, t) = \hat{n}(\vec{r}, t) m(\vec{r}, t) \quad (3)$$

of direction \hat{n} and magnitude m .

The physics also involves a self energy Σ which encodes the effects of scattering processes. We will distinguish two sources of scattering: spin conserving processes corresponding e.g. to scattering off of spin-independent random potentials and spin non-conserving processes:

$$\Sigma_{tot} = \Sigma_{cons} + \Sigma_{N-C} \quad (4)$$

We will assume that the spin non-conserving processes arise from electron exchange with a spin-unpolarized reservoir which does not change when a current is applied to the system.¹³ Thus Σ_{N-C} is proportional to the unit matrix in spin space and is independent of applied current. Because for example the density of states may be spin dependent Σ_{cons} may have structure in spin space. For simplicity we will assume that the magnetization varies sufficiently slowly in space that the electrons always relax to the local magnetization; in this case Σ_{cons} is the sum of a term proportional to the unit matrix and a term proportional to $\vec{m} \cdot \vec{\sigma}$ with, in particular, no terms proportional to gradients of \vec{m} . Where an explicit model is necessary we will take Σ_{cons} to arise from randomly placed point-like impurities.

We suppose that the system is driven out of equilibrium by an externally imposed current which is weak enough to be described by linear response theory. Since we are interested in length scales long compared to the spin relaxation length, any spin polarized current injected at the boundary will quickly relax. The relevant currents are thus induced by applying an electric field, \vec{E} . In the presence of a non-vanishing magnetization the resistivity ρ will be a matrix in spin space so the current density $\vec{J} = \rho^{-1} \vec{E}$ will have both a charge and a spin component. Our assumption that electrons are relaxed to the local magnetization direction means that the spin direction is aligned to the local magnetization so that in the basis aligned with the local magnetization ρ has components ρ_σ which may differ for up and down spins and (denoting the Cartesian component of a vector by a roman symbol)

$$\mathbf{J}^a = J_0^a \mathbf{1} + J_M^a \hat{n} \cdot \vec{\sigma} \quad (5)$$

In the Keldysh two contour Greens function method the current flowing between sites i and j is determined by the Keldysh component \mathbf{G}^K of the electron Greens function via

$$\mathbf{J}_{ij}^a = -i\mathbf{G}^K(i, j; t, t)J_{ji}^a \quad (6)$$

with current operator

$$\vec{J}_{i-j} = -it_{i-j}(\vec{r}_i - \vec{r}_j) \quad (7)$$

Here $(\vec{r}_i - \vec{r}_j)$ is the vector connecting sites i and j and in momentum space $\vec{J} = \partial\varepsilon_k/\partial\vec{k} \equiv \vec{v}_k$

The retarded and advanced components of the Greens function and self energy change only to second order in departures from equilibrium, so within the linear response approximation, departures from equilibrium may be described by nonequilibrium terms in the Keldysh components of the electron Greens function \mathbf{G} and self energy Σ . Thus we have e.g. $\mathbf{G}^K \rightarrow \mathbf{G}_{eq}^K + \mathbf{G}_{neq}^K$, with \mathbf{G}_{neq}^K calculated to linear order in the applied field. The nonequilibrium terms are discussed in detail in section IV; here we note simply that in a simple electronically three dimensional model with $k^2/2m$ dispersion, magnetization aligned along the spin- z axis and relatively weak scattering, the formalism leads to the familiar Drude formula

$$\rho_\sigma = \frac{m\Gamma_\sigma^{tot}}{n_\sigma} \quad (8)$$

with Γ_σ^{tot} the possibly spin-dependent scattering rate obtained from $Im\Sigma_{tot}(\omega=0)$ and n_σ the total number of electrons with spin aligned (or anti-aligned) to the local magnetic field.

Also, as discussed in Ref. 13 an applied electric field leads to a noise term corresponding to an effective temperature

$$T_{eff} = eEl^* \quad (9)$$

related to the voltage dropped over an appropriate length scale l^* . The differences in physics between the model considered here and the model studied in Ref. 13 will lead to a different expression for l^* .

C. Nonequilibrium terms in Greens function

In this subsection we sketch a derivation of the nonequilibrium terms in the electron Greens function and self energy. The treatment follows Ref. 13. Noting that the retarded and advance self energies are unchanged to linear order in applied fields, we parametrize the change in the Keldysh components of \mathbf{G} , Σ via a distribution function h related to the Greens function via $\mathbf{G}^K = \mathbf{G}^R h - h \mathbf{G}^A$ and similarly for Σ . We then follow the usual steps to obtain a quantum kinetic equation for h . In writing the kinetic equation we make use of our

assumption that the electron distribution relaxes to the local magnetization so that we have one kinetic equation for each spin direction. We further observe that in the model considered here, impurity scattering may relax the momentum dependence of the distribution function but not the energy dependence. We write $h = h_{eq} + h_A^\sigma + h_S^\sigma$ with $h_{eq}(x) = 1 - 2\Theta(-x)$ and nonequilibrium parts h_A odd and h_S even under $k \leftrightarrow -k$. Separating the even and odd parts of the kinetic equation we obtain (not denoting the spin direction explicitly)

$$\frac{\partial h_S}{\partial x} (\vec{E} \cdot \vec{v}) + 2\Gamma_{tot} h_A = -2\delta(x) (\vec{E} \cdot \vec{v}) \quad (10)$$

and

$$\frac{\partial h_A}{\partial x} \vec{E} \cdot \vec{v} + 2\Gamma_{N-C} h_S = 0 \quad (11)$$

Solving and restoring spin indices explicitly we find

$$h_A^\sigma = -\frac{\vec{E} \cdot \vec{v}}{\Gamma_{tot}^\sigma} \left(\frac{\sqrt{\Gamma_{N-C}\Gamma_{tot}^\sigma}}{|\vec{E} \cdot \vec{v}|} \text{Exp} \left[-\frac{2|x|\sqrt{\Gamma_{N-C}\Gamma_{tot}^\sigma}}{|\vec{E} \cdot \vec{v}|} \right] \right) \quad (12)$$

and

$$h_S^\sigma = -2\frac{\text{sgn}(x)}{2} \text{Exp} \left[-\frac{2|x|\sqrt{\Gamma_{N-C}\Gamma_{tot}^\sigma}}{|\vec{E} \cdot \vec{v}|} \right] \quad (13)$$

These expressions differ from those obtained in Ref. 13 because in that work $\Gamma^{tot} = \Gamma_{N-C}$.

For small E the term in parentheses in Eq. (12) is just an integral representation of the delta function $\delta(x)$. To an accuracy sufficient for the leading terms in the semiclassical expansion (Sec. III), Eq. (12) implies

$$\mathbf{G}_{neq}^K(i, l, \omega) = 2i\mathbf{G}^R(i-j, 0)\vec{J}_{j-k} \cdot \vec{E}\delta(\omega)\mathbf{G}^A(k-l, 0) \quad (14)$$

and

$$\Sigma_{neq}^K = 2i\vec{J}_{j-k} \cdot \vec{E}\delta(\omega) \quad (15)$$

For small E , h_S is just two powers of E times an integral representation of the derivative of the delta function so terms involving h_S would seem to give only contributions of higher order in E . But as shown in Ref. 13 and discussed in more detail below, the singularity in the $T=0$ equilibrium distribution function means that the h_S terms give a contribution of order $|E|$ to the noise. This issue will be further discussed in Section IV.

D. Path Integral Representation

We write the model as a path integral on the Keldysh two-time contour.^{1,27} For conducting systems which have magnetic ground states we expect that part of the interaction term may be decoupled by a Hubbard-Stratonovich transformation²⁶ while the remainder can

be treated by Fermi liquid theory. The important part of the Hubbard-Stratonovich field is a vector in spin space $\vec{m}(r, t) \cdot \vec{\sigma}$ which represents the local magnetization.

After integrating out the fermions we may express the model as a path integral

$$Z = \int \mathcal{D}\vec{m} e^{iS_F[\{m(r,t)\}] + iS_{int}[\{m(r,t)\}]} \quad (16)$$

In Eq. (16) we consider time as running along the full Keldysh contour (including forward and backward-moving parts and with 'Keldysh' time ordering assumed). The term $S_{int}[\{\vec{m}(r, t)\}]$ includes other terms in the energetics of the local spin polarization, including the terms arising from the Hubbard-Stratonovich transformation and the magnetic dipole energy. S_F , the logarithm of the fermion determinant, is

$$S_F = -iTr \ln [\mathbf{G}_0^{-1} - m\hat{\mathbf{n}}_i(t) \cdot \vec{\sigma}\tau_3 - \tau_3 \Sigma_{tot}\tau_3] \quad (17)$$

S_F depends on \mathbf{G}_0^{-1} , which is a matrix in space, time and Keldysh contour indices and expresses the effects of band structure and of Fermi liquid renormalizations. The matrix $\vec{\tau}$ acts in Keldysh space.

Following Schulz²⁶ we now rotate the spin quantization axis at each space-Keldysh time point so that it is parallel to $\hat{\mathbf{n}}$. The set of space-time rotation matrices which do this are $\mathbf{R}_{\hat{\mathbf{n}}}$ defined so that $\mathbf{R}_{\hat{\mathbf{n}}}^\dagger \hat{\mathbf{n}} \cdot \vec{\sigma} \mathbf{R}_{\hat{\mathbf{n}}} = \sigma_z$. Writing the spin orientation vector $\hat{n}(\vec{r}, t) = \cos\theta\hat{z} + \sin\theta\hat{u}$ with \hat{u} a vector in the $x-y$ plane, it is convenient to represent \mathbf{R} in terms of $\hat{\Omega}$ defined by

$$\hat{\Omega} = \left(\cos\frac{\theta}{2}\hat{z} + \sin\frac{\theta}{2}\hat{u} \right) \quad (18)$$

as

$$\mathbf{R} = \hat{\Omega}_z \mathbf{1} + i\hat{z} \times \hat{\Omega} \cdot \sigma \quad (19)$$

We obtain

$$S_F = -iTr \ln \left[\mathbf{R}_{\hat{\mathbf{n}}}^\dagger \mathbf{G}_0^{-1} \mathbf{R}_{\hat{\mathbf{n}}} - m\sigma_z - \mathbf{R}_{\hat{\mathbf{n}}}^\dagger \tau_3 \Sigma_{tot} \tau_3 \mathbf{R}_{\hat{\mathbf{n}}} \right] \quad (20)$$

The spin rotations correspond to an $SU(2)$ gauge transformation of the theory. If all of the terms in the underlying Hamiltonian are invariant under rotations of spin in the system of interest then the trace must be independent of the choice of spin quantization axis, corresponding to a gauge invariance of the model. Terms such as the local magnetization $m\hat{\mathbf{n}} \cdot \vec{\sigma}$ or sources (not explicitly written here) will break the $SU(2)$ invariance and lead to dependence on the spin directions. The reservoir which provides spin relaxation also breaks the $SU(2)$ gauge invariance because as we have defined it the rotation does not act on these degrees of freedom. Thus for example a time dependent spin rotation corresponds to a spin-dependent phase difference between system and reservoir, which could drive spin currents between the system of interest and the reservoir. A similar situation

obtains in the theory of dissipative effects in superconductors.^{19,28}

From Eq. (20), using $\mathbf{R}_{\hat{\mathbf{n}}}^\dagger \mathbf{R}_{\hat{\mathbf{n}}} = 1$, and defining the rotated frame Greens function \mathbf{G} via $\mathbf{G}^{-1} = (\mathbf{G}_0^{-1} - m\sigma_z - \tau_3 \Sigma \tau_3)$ we obtain

$$S_F = -iTr \ln [\mathbf{G}^{-1} + \delta\mathbf{H} - \delta\Sigma] \quad (21)$$

Here

$$\delta\mathbf{H} = \mathbf{R}_{\hat{\mathbf{n}}}^\dagger \mathbf{G}_0^{-1} \mathbf{R}_{\hat{\mathbf{n}}} - \mathbf{G}_0^{-1} \quad (22)$$

and

$$\delta\Sigma = \mathbf{R}_{\hat{\mathbf{n}}}^\dagger \tau_3 \Sigma \tau_3 \mathbf{R}_{\hat{\mathbf{n}}} - \tau_3 \Sigma \tau_3 \quad (23)$$

Assuming the magnetization varies slowly in space and expanding to second order in rotations gives

$$S = S_0 + S_1 + S_2 \quad (24)$$

with

$$S_0 = -iTr \ln [\mathbf{G}^{-1}] + S_{int} \quad (25)$$

$$S_1 = -iTr [\mathbf{G} (\delta\mathbf{H} - \delta\Sigma)] \quad (26)$$

$$S_2 = \frac{i}{2} Tr [\mathbf{G} (\delta\mathbf{H} - \delta\Sigma) \mathbf{G} (\delta\mathbf{H} - \delta\Sigma)] \quad (27)$$

At this point we write $\mathbf{G}, \Sigma \rightarrow \mathbf{G}_{eq} + \mathbf{G}_{neq}, \Sigma_{eq} + \Sigma_{neq}$ and retain terms up to first order in departures from equilibrium. Considering first the equilibrium terms we observe that our assumptions of non-magnetic scattering, slow variation of the magnetization and relaxation of quasiparticle distribution to the local magnetization imply that only the terms Σ_{N-C} arising from spin non-conserving quantities contribute to $\delta\Sigma_{eq}$:

$$\delta\Sigma_{eq} = \delta\Sigma_{N-C}^{eq} = \mathbf{R}_{\hat{\mathbf{n}}}^\dagger \tau_3 \Sigma_{N-C}^{eq} \tau_3 \mathbf{R}_{\hat{\mathbf{n}}} - \tau_3 \Sigma_{N-C}^{eq} \tau_3 \quad (28)$$

Thus for the equilibrium terms we have

$$\delta S^{eq} = S_1^{eq} + S_2^{eq} \quad (29)$$

with

$$S_1^{eq} = -iTr [\mathbf{G}_{eq} (\delta\mathbf{H} - \delta\Sigma_{N-C}^{eq})] \quad (30)$$

$$S_2^{eq} = \frac{i}{2} Tr \left[\mathbf{G}_{eq} (\delta\mathbf{H} - \delta\Sigma_{N-C}^{eq}) \times \mathbf{G}_{eq} (\delta\mathbf{H} - \delta\Sigma_{N-C}^{eq}) \right] \quad (31)$$

Here S_1^{eq} will be seen to give the basic Berry phase magnetization dynamics while S_2^{eq} gives the spin stiffness.

Turning now to the nonequilibrium terms, we work to leading order in both departures from equilibrium and rotations, neglecting the unimportant change in spin stiffness due to current flow. We obtain

$$S_1^{neq} = -iTr [\mathbf{G}_{neq} (\delta\mathbf{H} - \delta\Sigma_{N-C}^{eq})] + iTr [\mathbf{G}_{eq} \delta\Sigma_{neq}] \quad (32)$$

The rest of this paper is based on an evaluation of Eqs. (25), (30), (31), (32) in the presence of spin textures and externally imposed currents and in the limit of slow variation of spin direction. We perform an expansion in the amplitude of the quantum components of the rotation matrices. The leading terms in the semiclassical expansion give rise to the classical equations of motion for spin fluctuations and topological defects in the presence of an applied current. The next-to-leading terms lead to a current-induced effective temperature.

III. DRIVE AND DYNAMICS

A. Overview

In this section we present the leading terms in a semiclassical expansion. These terms give rise to the classical equations of motion for spin fluctuations and topological defects in the presence of an applied current. They are most easily obtained by going to the Larkin basis in contour space,²⁷ introducing classical (C) and quantum (Q) combinations of the time-ordered \mathbf{R}_2 and anti-time ordered \mathbf{R}_1 Keldysh contour fields via

$$\mathbf{R}_C = \frac{1}{2}(\mathbf{R}_2 + \mathbf{R}_1) \quad (33)$$

$$\mathbf{R}_Q = \frac{1}{2}(\mathbf{R}_2 - \mathbf{R}_1) \quad (34)$$

and expanding to leading order in \mathbf{R}_Q . We evaluate the terms in order.

B. S_1^{eq}

We first consider the terms involving δH . Expanding and taking the trace over contour indices gives

$$\begin{aligned} S_1^{eq, G_0} = & -iTr \left[\mathbf{G}^K(1-2)\mathbf{R}_C^\dagger(2)G_0^{A,-1}(2-1)\mathbf{R}_Q(1) \right. \\ & \left. + \mathbf{G}^K(1-2)\mathbf{R}_Q^\dagger(2)G_0^{R,-1}(2-1)\mathbf{R}_C(1) \right] \quad (35) \end{aligned}$$

where the trace is over space, time and spin degrees of freedom.

Now $G_0^{R,-1}(\vec{r}_1 - \vec{r}_2; t_1 - t_2) = \delta(t_1 - t_2) \left(i\vec{\partial}_t - t_{ij} \right)$ and $G_0^{A,-1}(\vec{r}_1 - \vec{r}_2; t_1 - t_2) = \left(-i\overleftarrow{\partial}_t - t_{ij} \right) \delta(t_1 - t_2)$ are short ranged in space and time so we may perform a gradient expansion of Eq. (35). Because $\mathbf{R}_Q^\dagger(1)\mathbf{R}_C(1) + \mathbf{R}_C^\dagger(1)\mathbf{R}_Q(1) = (\mathbf{R}_2^\dagger(1)\mathbf{R}_2(1) - \mathbf{R}_1^\dagger(1)\mathbf{R}_1(1))/2$ vanishes, the leading terms are the first derivatives. The space derivative term vanishes because in equilibrium G^K is an even function of its space arguments. Thus we obtain

$$\begin{aligned} S_1^{eq, G_0} = & -iTr \left[\mathbf{G}_0^K \left(\{ -i\partial_t \mathbf{R}_C^\dagger \} \mathbf{R}_Q + \mathbf{R}_Q^\dagger \{ i\partial_t \mathbf{R}_C \} \right) \right] \\ & -i\mathbf{G}_0^K \equiv -i\mathbf{G}^K(i, i; t, t) = \rho + m\sigma^z \text{ with } \rho \text{ a scalar related to the charge density and } m \text{ the magnitude of the magnetization on site } i \text{ at time } t. \hat{z} \text{ is the (arbitrarily chosen) spin quantization axis.} \quad (36) \end{aligned}$$

We next consider the term in S_1^{eq} arising from the equilibrium self energy. Expressing the result in the Larkin basis, taking the trace and retaining only the terms with one quantum field gives (here we leave the trace over spin, space and time labels implicit, denote spin matrix structure in bold and collapse the space and time indices):

$$\begin{aligned} S_{1,eq}^\Sigma = & iTr \left[\mathbf{G}^R(1-2)\mathbf{R}_C^\dagger(2)\Sigma_{N-C}^K(2-1)\mathbf{R}_Q(1) + \mathbf{G}^K(1-2)\mathbf{R}_C^\dagger(2)\Sigma_{N-C}^A(2-1)\mathbf{R}_Q(1) \right. \\ & \left. + \mathbf{G}^A(1-2)\mathbf{R}_Q^\dagger(2)\Sigma_{N-C}^K(2-1)\mathbf{R}_C(1) + \mathbf{G}^K(1-2)\mathbf{R}_Q^\dagger(2)\Sigma_{N-C}^R(2-1)\mathbf{R}_C(1) \right] \quad (37) \end{aligned}$$

Our assumption of spin-independent reservoirs means that $\Sigma^{R,A,K}$ are scalars in spin space so may be factored out, leaving

$$S_{1,eq}^\Sigma = i\mathbf{D}_{CQ}(1-2)\mathbf{R}_C^\dagger(2)\mathbf{R}_Q(1) + (Q \leftrightarrow C) \quad (38)$$

Here,

$$\mathbf{D}_{CQ} = \mathbf{G}^R(1-2)\Sigma_{N-C}^K(2-1) + \mathbf{G}^K(1-2)\Sigma_{N-C}^A(2-1) \quad (39)$$

and

$$\mathbf{D}_{QC} = \mathbf{G}^A(1-2)\Sigma_{N-C}^K(2-1) + \mathbf{G}^K(1-2)\Sigma_{N-C}^R(2-1) \quad (40)$$

Since $G^{R/A}$ and $\Sigma_{N-C}^{R/A}$ are short ranged in space and time we can make a gradient expansion of the product of rotation matrices, writing $\mathbf{R}_C^\dagger(2) = \mathbf{R}_C^\dagger(1) + (2-1)\partial\mathbf{R}_C^\dagger(1) + \mathcal{O}(1-2)^2$ and $\mathbf{R}_C(1) = \mathbf{R}_C(2) + (1-2)\partial\mathbf{R}_C(2) + \mathcal{O}(1-2)^2$. We then change labels ($1 \leftrightarrow 2$) in the second term and obtain

$$\int d2 \left[\mathbf{D}_{CQ}(1-2)\mathbf{R}_C^\dagger(1)\mathbf{R}_Q(1) + \mathbf{D}_{QC}(1-2)\mathbf{R}_Q^\dagger(1)\mathbf{R}_C(1) \right] \quad (41)$$

Since $\int d2 D_{CQ}(1-2) = \int d2 D_{QC}(1-2)$, the leading term vanishes while the even parity of the equilibrium state means the first space derivative vanishes. So the leading term is the first time derivative and incorporating the i into the coefficients we obtain

$$S_{1,eq}^\Sigma = Tr \left[\mathbf{D}'_{CQ} \partial_t \mathbf{R}_C^\dagger(1) \mathbf{R}_Q(1) + \mathbf{D}'_{QC} \mathbf{R}_Q^\dagger(1) \partial_t \mathbf{R}_C(1) \right] \quad (42)$$

with

$$\mathbf{D}'_{CQ} = i \int d2(t_2 - t_1) \mathbf{D}_{CQ}(\vec{r}_1 - \vec{r}_2, t_1 - t_2) \quad (43)$$

$$\mathbf{D}'_{QC} = i \int d2(t_1 - t_2) \mathbf{D}_{QC}(\vec{r}_1 - \vec{r}_2, t_1 - t_2) \quad (44)$$

The coefficients are most conveniently evaluated in Fourier space as $\mathbf{D}'_{CQ} = \partial \mathbf{D}_{CQ}(\Omega)/\partial \Omega|_{\Omega=0}$ and $\mathbf{D}'_{QC} = -\partial \mathbf{D}_{QC}(\Omega)/\partial \Omega|_{\Omega=0}$. Introducing

$$\mathbf{G}' = \frac{1}{2} (\mathbf{G}^A(1-2) + \mathbf{G}^R(1-2)) \quad (45)$$

$$\mathbf{A} = \frac{1}{2i} (\mathbf{G}^A(1-2) - \mathbf{G}^R(1-2)) \quad (46)$$

$$\Sigma'_{N-C} = \frac{1}{2} (\Sigma_{N-C}^A(1-2) + \Sigma_{N-C}^R(1-2)) \quad (47)$$

$$\Gamma_{N-C} = \frac{1}{2i} (\Sigma_{N-C}^A(1-2) - \Sigma_{N-C}^R(1-2)) \quad (48)$$

and noting that in equilibrium we have $G^K(k, \omega) = -2iA(k, \omega)h(\omega)$ and $\Sigma_{N-C}^K(k, \omega) = -2i\Gamma_{N-C}(k, \omega)h(\omega)$ with h the equilibrium distribution function we find

$$D_{CQ}(\Omega) = D_1(\Omega) - iD_2(\Omega) \quad (49)$$

$$D_{QC}(\Omega) = -D_1(\Omega) - iD_2(\Omega) \quad (50)$$

with the real functions D_1 and D_2 given by

$$D_1(\Omega) = 2 \int (dk d\omega) \mathbf{A}(k, \omega + \Omega) \Gamma_{N-C}(k, \omega) \times (h(\omega + \Omega) - h(\omega)) \quad (51)$$

and

$$D_2(\Omega) = 2 \int (dk d\omega) \left[\mathbf{G}'(k, \omega + \Omega) \Gamma_{N-C}(k, \omega) h(\omega) + \mathbf{A}(k, \omega + \Omega) \Sigma'_{N-C}(k, \omega) h(\omega + \Omega) \right] \quad (52)$$

Thus, $D_{CQ}(\Omega = 0) = D_{QC}(\Omega = 0)$ as noted above. We therefore obtain

$$S_{1,eq}^\Sigma = \sum_i \int dt \left(\mathbf{D}_{berry} \left(-i \partial_t \mathbf{R}_C^\dagger(i, t) \mathbf{R}_Q(i, t) + \mathbf{R}_Q^\dagger(i, t) i \partial_t \mathbf{R}_C(i, t) \right) + \mathbf{D}_{diss} \left(\partial_t \mathbf{R}_C^\dagger(i, t) \mathbf{R}_Q(i, t) + \mathbf{R}_Q^\dagger(i, t) \partial_t \mathbf{R}_C(i, t) \right) \right) \quad (53)$$

with

$$\mathbf{D}_{diss} = \frac{\partial D_1}{\partial \Omega} = \frac{2}{\pi} \int (dk) \mathbf{A}(k, \omega = 0) \Gamma_{N-C}(k, \omega = 0) \quad (54)$$

and, using the Kramers-Kronig relation and shifting $\omega \rightarrow \omega - \Omega$ appropriately,

$$\mathbf{D}_{berry} = -2 \int (d\omega dx) (dk) \frac{\mathbf{A}(k, x) \Gamma_{N-C}(k, \omega) (h(\omega) - h(x))}{(\omega - x)^2} \quad (55)$$

The \mathbf{D}_{berry} term appears as a renormalization of Eq. (36) while the \mathbf{D}_{diss} term parametrizes effects of dissipation. In the rotated basis both terms are diagonal matrices in spin space and are explicitly proportional to the spin relaxation rate Γ_{N-C} . Additional terms would appear if the reservoir was magnetic.

We have written Eq. (54) for the general case. Our specific results are presented for a momentum-independent spin relaxation rate. For this case the Γ_{N-C} may be removed from the integral and we identify $\int (dk) A(k, \omega = 0)$ as the spin-dependent Fermi level density of states N_σ . In a simple model with $k^2/2m$ dispersion, $N_\sigma = mk_{F,\sigma}/(2\pi^2)$. Thus we estimate that the diagonal matrix elements D^σ are

$$D_{diss}^\sigma = \frac{3}{\pi} \frac{n_\sigma \Gamma_{N-C}}{E_{F,\sigma}} \quad (56)$$

with $E_{F,\sigma} = k_{F,\sigma}^2/2m$ the Fermi energy for spin direction σ .

C. S_2^{eq}

Expanding S_2^{eq} , Eq. (31), gives the standard spin-stiffness terms, renormalized weakly by the coupling to the reservoir. These may be written (reverting here to the physical spin coordinates)

$$S_{stiffness} = i\rho_S \int dx dt \hat{\mathbf{n}}_q \cdot \vec{\nabla}^2 \hat{\mathbf{n}}_{cl,\perp}(x, t) \quad (57)$$

where $\hat{\mathbf{n}}_{cl,\perp}(x, t)$ is the classical component of \hat{n} perpendicular to the local magnetization direction and ρ_S is the spin stiffness, proportional to the local magnetization.

D. Nonequilibrium terms

We first consider the first term in Eq. (32). Expanding as in the previous section we find terms of the form of Eq. (35) but with \mathbf{G}^K replaced by the nonequilibrium Keldysh function and terms of the form of Eq. (37) with the $G^{R,A}$ terms removed and the \mathbf{G}^K replaced by the nonequilibrium Keldysh function. The terms of the form of Eq. (35) are

$$S_2^{neq, G_0} = -iTr \left[\mathbf{G}_{neq}^K(1-2)\mathbf{R}_C^\dagger(2)G_0^{A,-1}(2-1)\mathbf{R}_Q(1) + \mathbf{G}_{neq}^K(1-2)\mathbf{R}_Q^\dagger(2)G_0^{R,-1}(2-1)\mathbf{R}_C(1) \right] \quad (58)$$

Since the nonequilibrium \mathbf{G}_{neq}^K is an odd function of its space coordinates but an even function of time the only non-vanishing contribution comes from the hopping terms in $\delta\mathbf{H}$. We obtain

$$S_2^{neq, G_0} = iTr \left[\mathbf{G}_{neq}^K(i, j; t) t_{j-i} \times \left(\mathbf{R}_C^\dagger(j, t)\mathbf{R}_Q(i, t) + \mathbf{R}_Q^\dagger(j, t)\mathbf{R}_C(i, t) \right) \right] \quad (59)$$

Writing $\mathbf{R}_C^\dagger(j) = (\vec{r}_j - \vec{r}_i)^a \nabla^a \mathbf{R}_C^\dagger(i)$ and $\mathbf{R}_C(i) = (\vec{r}_i - \vec{r}_j)^a \nabla^a \mathbf{R}_C(j)$, changing i to j in the second term and using Eqs. (6), (7) we obtain

$$S_2^{neq, G_0} = -iTr \left[\mathbf{J}^a \left(\nabla^a \mathbf{R}_C^\dagger(i, t)\mathbf{R}_Q(i, t) - \mathbf{R}_Q^\dagger(i, t)\nabla^a \mathbf{R}_C(i, t) \right) \right] \quad (60)$$

We next consider the terms arising from Σ_{eq} . These are of the form of Eq. (37) but with the functions $D_{QC/eq}$ replaced by

$$E_{CQ} = \mathbf{G}_{neq}^K(1-2)\Sigma_{N-C}^A(2-1) \quad (61)$$

and

$$E_{QC} = \mathbf{G}_{neq}^K(1-2)\Sigma_{N-C}^R(2-1) \quad (62)$$

Making the gradient expansion as above gives

$$Tr \left[\mathbf{E}_{CQ}^a \nabla^a \mathbf{R}_C^\dagger(1)\mathbf{R}_Q(1) + \mathbf{E}_{QC}^a \mathbf{R}_Q^\dagger(1)\nabla^a \mathbf{R}_C(1) \right] \quad (63)$$

with

$$\mathbf{E}_{CQ}^a = i \int d2(\vec{r}_2 - \vec{r}_1)^a \mathbf{E}_{CQ}(\vec{r}_1 - \vec{r}_2, t_1 - t_2) \quad (64)$$

$$\mathbf{E}_{QC}^a = i \int d2(\vec{r}_1 - \vec{r}_2)^a \mathbf{E}_{QC}(\vec{r}_1 - \vec{r}_2, t_1 - t_2) \quad (65)$$

In the limit of momentum-independent (space local) spin relaxation rates which we consider here these terms vanish, but in general there will be a contribution proportional to $\partial_k \Sigma_{N-C}$.

In the second term in Eq. (32), use of the steps leading to Eq. (37) along with the fact that Σ_{neq} has only a Keldysh component and is proportional to the unit tensor in spin space gives (leaving the sum over coordinates implicit)

$$S_{1,neq}^\Sigma = i\mathbf{F}_{CQ}(1-2)\mathbf{R}_C^\dagger(2)\mathbf{R}_Q(1) + i\mathbf{F}_{QC}(1-2)\mathbf{R}_Q^\dagger(2)\mathbf{R}_C(1) \quad (66)$$

with

$$\mathbf{F}_{CQ} = \mathbf{G}^R(1-2)\Sigma_{neq}^K(2-1) \quad (67)$$

and

$$\mathbf{F}_{QC} = \mathbf{G}^A(1-2)\Sigma_{neq}^K(2-1) \quad (68)$$

Again making the gradient expansion and incorporating the i into the coefficients we find

$$\delta S_{1,neq,\Sigma}^\Sigma = \mathbf{F}_{CQ}^a \nabla^a \mathbf{R}_C^\dagger(1)\mathbf{R}_Q(1) + \mathbf{F}_{QC}^a \mathbf{R}_Q^\dagger(1)\nabla^a \mathbf{R}_C(1) \quad (69)$$

The explicit form of Σ_{neq}^K (Eq. (15)) gives, in a mixed position-frequency representation

$$\mathbf{F}_{CQ}^a = \frac{i}{\pi} \sum_j \mathbf{G}^R(i-j, \omega=0) t_{j-i} \vec{r}_{ji}^a \left(\vec{r}_{ji} \cdot \vec{E} \right) \quad (70)$$

$$\mathbf{F}_{QC}^a = \frac{i}{\pi} \sum_j \mathbf{G}^A(i-j, \omega=0) t_{j-i} \vec{r}_{ij}^a \left(\vec{r}_{ji} \cdot \vec{E} \right) \quad (71)$$

Here \vec{r}_{ij} is the vector connecting site i to site j and in the QC term we have \vec{r}_{ij}^b not \vec{r}_{ji}^b because we put the gradient on the R_C . In Fourier space we have

$$\mathbf{F}_{CQ}^a = \frac{i}{\pi} \int (dk) \mathbf{G}^R(k, \omega=0) \frac{\partial^2 \varepsilon_k}{\partial k_a \partial k_b} E^b \quad (72)$$

$$\mathbf{F}_{QC}^a = -\frac{i}{\pi} \int (dk) \mathbf{G}^A(k, \omega=0) \frac{\partial^2 \varepsilon_k}{\partial k_a \partial k_b} E^b \quad (73)$$

Our final expression therefore is

$$S_{1,neq}^\Sigma = \sum_i \int dt \left[i\mathbf{F}_J^a \left(-\nabla^a \mathbf{R}_C^\dagger(i, t)\mathbf{R}_Q(i, t) + \mathbf{R}_Q^\dagger(i, t)\nabla^a \mathbf{R}_C(i, t) \right) + \mathbf{F}_{diss}^a \left(\nabla^a \mathbf{R}_C^\dagger(i, t)\mathbf{R}_Q(i, t) + \mathbf{R}_Q^\dagger(i, t)\nabla^a \mathbf{R}_C(i, t) \right) \right] \quad (74)$$

with the \mathbf{F} diagonal matrices in spin space with up and down spin components (here we use the resistivity to express the electric field in terms of the current)

$$F_{J,\sigma}^a = -\frac{1}{\pi} \int (dk) \mathcal{R}e G_\sigma^R(k, \omega=0) \frac{\partial^2 \varepsilon_k}{\partial k_a \partial k_b} \rho_\sigma J_\sigma^b \quad (75)$$

$$F_{diss,\sigma}^a = \frac{1}{\pi} \int (dk) A_\sigma(k, \omega=0) \frac{\partial^2 \varepsilon_k}{\partial k_a \partial k_b} \rho_\sigma J_\sigma^b \quad (76)$$

It will be useful for our further discussion to estimate the magnitudes of F^a in a simple model with $k^2/2m$ dispersion. In this case $\partial^2 \varepsilon_k / \partial k_a \partial k_b = \delta^{ab}/m$ and the estimates that led to Eq. (56) along with Eq. (8) give

$$F_{diss,\sigma}^a = \frac{3\Gamma_{\sigma}^{tot}}{2\pi E_{F,\sigma}} J^a \quad (77)$$

IV. SECOND ORDER IN QUANTUM FIELDS: NOISE TERMS

Expanding the action to second order in quantum fields yields terms which stabilize the integral over quantum fields and, among other effects, introduce an effective temperature into the problem. A general analysis of these terms is somewhat involved; we focus here on obtaining the qualitative behavior at $T=0$ and to leading order in the gradient expansion. In this case the equilibrium terms do not contribute and expanding Eq. (32) to second order in \mathbf{R}_Q yields

$$S_{noise} = iTr \left[\mathbf{G}_{eq}^K \mathbf{R}_Q^\dagger \Sigma_{neq}^K \mathbf{R}_Q + \mathbf{G}_{neq}^K \mathbf{R}_Q^\dagger \Sigma_{eq}^K \mathbf{R}_Q \right] \quad (78)$$

For simplicity we assume that the spin-nonconserving scattering rate is small compared to the total scattering rate, so that the first term is dominant. We then obtain

$$S_{noise} = iT^* \sum_i \int dt Tr \left[\mathbf{N} \mathbf{R}_Q^\dagger(i, t) \mathbf{\Gamma}^{tot} \mathbf{R}_Q(i, t) \right] \quad (79)$$

\mathbf{N} is a diagonal matrix with entries $N_\sigma = \frac{2}{\pi} \int (dk) |\cos \phi_k| A_\sigma(k, \omega=0)$, ϕ_k is the angle between \vec{v}_k and \vec{E} , $\mathbf{\Gamma}$ is a diagonal matrix with entries $\sqrt{\Gamma_\sigma^{tot} \Gamma^{tot}}$ with

$$\Gamma^{tot} = \frac{\Gamma_\uparrow^{tot} + \Gamma_\downarrow^{tot}}{2} \quad (80)$$

and the effective temperature is

$$T^* = \frac{|\vec{E}| |\vec{v}_F|}{\sqrt{\Gamma_{N-C} \Gamma^{tot}}} \quad (81)$$

As in Ref. 13, the effective temperature is given by the voltage drop over the distance traveled between inelastic scattering events.

V. SUMMARY OF ACTION

Collecting all of the terms we obtain an action in terms of the classical and quantum rotation fields of the form

$$S_F[\{\mathbf{R}^\dagger, \mathbf{R}\}] = S_B + S_{diss} + S_{stiffness} + S_{noise} \quad (82)$$

with

$$S_B = \sum_\mu Tr \left[\mathbf{B}_\mu \left\{ \mathbf{R}_Q^\dagger (i\partial_\mu \mathbf{R}_C) - (i\partial_\mu \mathbf{R}_C^\dagger) \mathbf{R}_Q \right\} \right], \quad (83)$$

$$S_{diss} = \sum_\mu Tr \left[\mathbf{D}_\mu \left\{ \mathbf{R}_Q^\dagger (\partial_\mu \mathbf{R}_C) + (\partial_\mu \mathbf{R}_C^\dagger) \mathbf{R}_Q \right\} \right] \quad (84)$$

$S_{stiffness}$ is given by Eq. (57) and S_{noise} by Eq. (79). Here $\mu=0$ denotes the time direction and $\mu=a$ a space direction.

We have

$$\mathbf{B}_0 = m\sigma_z + \mathbf{D}_{berry} \quad (85)$$

$$\mathbf{B}_a = \mathbf{J}^a + \mathbf{F}_J^a \quad (86)$$

$$\mathbf{D}_0 = \mathbf{D}_{diss} \quad (87)$$

$$\mathbf{D}_a = \mathbf{F}_{diss}^a \quad (88)$$

Bold-face coefficients denote matrices in spin space; the spin structure arises from spin dependence of the density of states and scattering rate in the presence of a non-vanishing local magnetization.

We now use Eq. (18) to express Eq. (84) in terms of the classical and quantum components of the unit vectors $\hat{\Omega}$. We have

$$\mathbf{R}_Q = \hat{\Omega}_Q^z \mathbf{1} + i\hat{z} \times \hat{\Omega}_Q^\perp \cdot \vec{\sigma} \quad (89)$$

and

$$\partial_\mu \mathbf{R}_C = \frac{\partial \mathbf{R}_C}{\partial \hat{\Omega}^b} \partial_\mu \hat{\Omega}^b \quad (90)$$

The action is thus of the form

$$S_F = \Omega_Q^a J_\mu^{ab} \partial_\mu \Omega_C^b + \Omega_Q^a D_\mu^{ab} \partial_\mu \Omega_C^b + iT^* \Omega_Q^a N^{ab} \Omega_C^b + S_{stiffness} \quad (91)$$

with

$$J_\mu^{ab} = iTr \left[\mathbf{B}_\mu \left(\frac{\partial \mathbf{R}_C^\dagger}{\partial \hat{\Omega}^a} \frac{\partial \mathbf{R}_C}{\partial \hat{\Omega}^b} - \frac{\partial \mathbf{R}_C^\dagger}{\partial \hat{\Omega}^b} \frac{\partial \mathbf{R}_C}{\partial \hat{\Omega}^a} \right) \right] \quad (92)$$

$$D_\mu^{ab} = Tr \left[\mathbf{D}_\mu \left(\frac{\partial \mathbf{R}_C^\dagger}{\partial \hat{\Omega}^a} \frac{\partial \mathbf{R}_C}{\partial \hat{\Omega}^b} + \frac{\partial \mathbf{R}_C^\dagger}{\partial \hat{\Omega}^b} \frac{\partial \mathbf{R}_C}{\partial \hat{\Omega}^a} \right) \right] \quad (93)$$

and

$$N^{zz} = 2 \frac{N_\uparrow \Gamma_\uparrow^{tot} + N_\downarrow \Gamma_\downarrow^{tot}}{2} \quad (94)$$

$$N^{xx} = N^{yy} = 2 \frac{N_\uparrow \Gamma_\downarrow^{tot} + N_\downarrow \Gamma_\uparrow^{tot}}{2} \quad (95)$$

Evaluating the derivatives explicitly and noting that J^{ab} and D^{ab} have terms $\sim \mathbf{1}$ and $\sim \sigma_z$ we find

$$J_\mu^{xy} = -J_\mu^{yx} = 2\mathcal{J}_\mu \quad (96)$$

with all other elements of $J_\mu=0$, while

$$D_\mu^{ab} = \mathcal{D}_\mu \delta^{ab} \quad (97)$$

We thus have

$$S_B + S_{diss} = \hat{\Omega}_Q \cdot \left(-\hat{z} \times (\mathcal{J}_\mu \partial_\mu) \hat{\Omega}_C + (\mathcal{D}_\mu \partial_\mu) \hat{\Omega}_C \right) \quad (98)$$

with $\mu = 0$, a labeling space-time components and

$$\mathcal{J}_0 = m + 2Tr[\sigma_z \mathbf{D}_{berry}] \quad (99)$$

$$\mathcal{J}_a = 2Tr[\sigma_z (\mathbf{J}^a + \mathbf{F}_J^a)] \quad (100)$$

$$\mathcal{D}_0 = 2Tr[\mathbf{D}_{diss}] \quad (101)$$

$$\mathcal{D}_a = 2Tr[\mathbf{F}_{diss}^a] \quad (102)$$

The estimates provided above imply

$$\mathcal{J}_0 \sim m \quad (103)$$

$$\vec{\mathcal{J}} \sim \vec{J}_M \sim m\vec{J} \quad (104)$$

$$\mathcal{D}_0 \sim \frac{\Gamma_{N-C}}{E_F} \quad (105)$$

$$\vec{\mathcal{D}} \sim \frac{\Gamma^{tot}}{E_F} \vec{J} \quad (106)$$

The coefficient of Ω_Q in Eq. (98) gives the classical equation of motion for an isolated spin in the presence of dissipation and current drive. It is consistent with previous derivations based on the phenomenological Landau-Lifshitz-Gilbert equation,^{16,17,22} and with microscopic derivations of the Landau-Lifshitz equations in the presence of current.^{23,25} Here the terms proportional to \mathcal{J} are non-dissipative terms giving rise to the adiabatic spin torque and arising from the usual Berry phase, as modified by an applied current,^{18,21,29} while the terms involving \mathcal{D} arise from dissipative processes and give rise to the nonadiabatic spin torque.²²

The Galilean transformation

$$\vec{r} \rightarrow \vec{r} - \vec{u}_s t \quad (107)$$

with

$$\vec{u}_s = \frac{\vec{\mathcal{J}}}{\mathcal{J}_0} \quad (108)$$

shifts to a frame co-moving with the spin current. In this reference frame the spatial derivative terms in S_B vanish. The coefficient of the spatial derivative in the combination of S_{diss} becomes

$$\mathcal{D}_0 (\vec{u}_n - \vec{u}_s) \quad (109)$$

with normal velocity

$$\vec{u}_n = \frac{\vec{\mathcal{D}}}{\mathcal{D}_0} \quad (110)$$

In a Galilean invariant theory this combination vanishes. The easiest way to achieve Galilean invariance is to remove the scattering, so $\mathcal{D}_\mu = 0$, however one may also imagine a situation in which $\vec{u}_n = \vec{u}_s$. However, the estimates given above show that in the general case, in the co-moving frame the coefficient of the spatial derivative in the \mathcal{D} term is of order of the difference between the transport and spin relaxation rates (measured relative to the Fermi energy)

$$\frac{\Gamma_{N-C} - \Gamma^{tot}}{E_F} \vec{J} \quad (111)$$

Because we generically expect a spin relaxation rate much less than the transport relaxation rate, Galilean invariance is strongly broken in general.

VI. EQUATION OF MOTION FOR A TOPOLOGICAL DEFECT

A. Overview

To obtain the equation of motion of a vortex we imagine that spin wave excitations can be integrated out so that the spin orientation \mathbf{n} is determined by topological defects at positions $\vec{X}^j(t)$. We further suppose that the topological defects move slowly enough that the spins are relaxed to the values appropriate to the instantaneous position of the defects. We have (repeated indices summed)

$$\hat{\Omega}_Q = \frac{\delta \hat{\Omega}}{\delta X_{C,j}^a} X_{Q,j}^a \quad (112)$$

Then we may rewrite Eq. (98) as

$$S = \int dt \sum_{ia} X_{Q,i}^a(t) \mathcal{F}_i^a(t) + \sum_{ijab} X_{Q,i}^a(t) \mathcal{L}_{ij}^{ab}(t) \dot{X}_{C,j}^b(t) + i \sum_{ij} X_{Q,i}^a(t) \Xi^{ab} X_{Q,j}^b(t) \quad (113)$$

Here the noise term

$$\Xi^{ab} = T^* \frac{\delta \hat{\Omega}^\mu}{\delta X_{C,i}^a} N^{\mu\nu} \frac{\delta \hat{\Omega}^\nu}{\delta X_{C,j}^b} \quad (114)$$

The generalized force \mathcal{F} and Liouville operator \mathcal{L} are formally given by

$$\begin{aligned} \mathcal{F}_i^a(t) &= \int (dr) \hat{z} \cdot \frac{\delta \hat{\Omega}}{\delta X_{C,i}^a} \times (\vec{\mathcal{J}} \cdot \vec{\nabla} \hat{\Omega}) \\ &+ \frac{\delta \hat{\Omega}}{\delta X_{C,i}^a} \cdot (\vec{\mathcal{D}} \cdot \vec{\nabla} \hat{\Omega}) - \sum_j \frac{\partial U(\vec{X}_{C,i} - \vec{X}_{C,j})}{\partial X_{C,i}^a} \end{aligned} \quad (115)$$

$$\mathcal{L}_{ij}^{ab}(t) = \int (dr) \mathcal{J}_0 \hat{z} \cdot \frac{\delta \hat{\Omega}}{\delta X_{C,i}^a} \times \frac{\delta \hat{\Omega}}{\delta X_{C,j}^b} + \mathcal{D}_0 \frac{\delta \hat{\Omega}}{\delta X_{C,i}^a} \cdot \frac{\delta \hat{\Omega}}{\delta X_{C,j}^b} \quad (116)$$

Here $\hat{\Omega}$, \hat{z} denote unit vectors in spin space. They depend on all of the vortex positions, although this dependence is not explicitly notated. The $\vec{\nabla}$ are vectors in position space. Except for the terms in parentheses in Eq. (115) the dot and cross product structure refers to the spin directions. $\vec{\mathcal{J}}$ is the spin current produced by an applied electric field. The direction of current flow (indicated by the vector symbol) is along the applied electric

field while the spin direction is parallel to the local magnetization. \vec{D} is also directed along the applied electric field. U is the interdefect potential arising from the spin stiffness and dipolar forces.

The equation of motion for vortex i is obtained in the usual way²⁷ by using a Lagrange multiplier to integrate out the quantum fields, leading to

$$\eta \mathcal{C} \mathcal{J}_0 \hat{z} \times \dot{\vec{X}} + I_D \mathcal{D}_0 \dot{\vec{X}}_i = \eta \mathcal{C} \hat{z} \times \vec{\mathcal{J}} + I_D \vec{D} + \sum_j \vec{F}_{ij} + \vec{\zeta}_i \quad (117)$$

with $\vec{F}_{ij} = -\vec{\nabla}_{ij} U(\vec{X}_i - \vec{X}_j)$, $\eta = \pm 1$ the sign of the vorticity and ζ_i a fluctuating field which on scales longer than the mean free path may be taken to be delta correlated, with

$$\langle \zeta_i^a(t) \zeta_j^b(t') \rangle = 2\Xi_{ij}^{ab} \delta(t - t') \quad (118)$$

Eq. (117) is consistent with derivations based on the phenomenological Landau-Lifshitz-Gilbert equation.^{16,17}

In the remainder of this section we examine separately the drive terms (those arising due to the presence of an imposed current and visible in the equation of motion for a single topological defect) and the intervortex interaction terms.

B. Drive terms

We examine Eq. (116) for a two dimensional system containing a single vortex, at a position $\vec{X}(t) = X(t)\vec{e}_x + Y(t)\vec{e}_y$. In this case $\Omega \rightarrow \Omega(\vec{r} - \vec{X}(t))$ so $\delta\hat{\Omega}/\delta X^a = -\nabla^a \hat{\Omega}$ and Eqs. (115), (116) involve two quantities:

$$I_J = \int d^2r \mathcal{M}(r) \left(\nabla_x \hat{\Omega}_x \nabla_y \hat{\Omega}_y - \nabla_x \hat{\Omega}_y \nabla_y \hat{\Omega}_x \right) \quad (119)$$

$$I_D^{ab} = \int d^2r \nabla_a \hat{\Omega} \cdot \nabla_b \hat{\Omega} \quad (120)$$

with \mathcal{M} proportional to the magnetization a function to be discussed below. I_J and I_D depend on the structure of the vortex. We consider here an easy-plane system with spins lying preferentially in the $x - y$ plane and choose the origin of coordinates to be the position of the vortex.

Far from the vortex, \mathcal{M} is a constant proportional to the local magnetization and the spin orientation vector is $\hat{n}_x = \cos\eta\phi$, $\hat{n}_y = \sin\eta\phi$ and $\hat{n}_z = 0$, implying $\Omega_z = \frac{1}{\sqrt{2}}$ and $(\Omega_x, \Omega_y) = \frac{1}{\sqrt{2}}(\cos\eta\phi, \sin\eta\phi)$. Within a distance ξ of the vortex the structure changes. The integral defining I_D is dominated by the far region. Substituting we have

$$I_D^{ab} = \pi\eta^2 \delta^{ab} \ln \frac{L}{\xi} + \dots = I_D \delta^{ab} \quad (121)$$

with the ellipsis denoting terms of order 1. In a system with a single vortex the long distance cutoff is the system size; in a system with equal densities of vortices and antivortices the cutoff is the mean intervortex spacing. This logarithm has been previously noted.²⁹

The noise term may be evaluated similarly. The leading behavior is also logarithmic and arises from the case where i and j refer to the same vortex; we estimate $\Xi_{ij}^{ab} = \Xi^a \delta_{ij}^{ab}$ with

$$\Xi^a = I_D N^{aa} T^* \quad (122)$$

and Ξ^z of order unity. Here T^* is given in Eq. (81). Note that in a fully polarized (half-metallic) magnet, $N^{xx} = 0$ and the dissipation vanishes in this approximation (higher order processes will lead to a non-zero, but much smaller, noise).

Turning now to I_J we see that the contributions from the far region vanish so I_J is determined by the properties of the vortex core, which depends upon details. Two simplifying limits are possible. In the extreme soft spin, high anisotropy limit, the core is defined by a vanishing of the local magnetization amplitude (represented here by $\mathcal{M} \rightarrow 0$) while the spin vector remains in the easy plane. In this case $I_J = 0$. On the other hand, in the hard spin, weak anisotropy limit the spin amplitude remains constant, and the spin direction rotates out of the plane, becoming parallel (or anti-parallel) to z . In a general situation both effects occur, with the relative importance controlled by the ratio of the magnetic anisotropy energy to the amplitude energy.

Going to polar $(r - \phi)$ coordinates we have $\hat{\Omega}_x = \sin \frac{\theta(r)}{2} \cos \eta \phi$ and $\hat{\Omega}_y = \sin \frac{\theta(r)}{2} \sin \eta \phi$ so

$$I_J = \int d^2r \mathcal{M}(r) \left\{ \left(\frac{d\theta}{2dr} \cos \frac{\theta}{2} \cos^2 \eta \phi + \frac{\eta}{r} \sin \frac{\theta}{2} \sin^2 \eta \phi \right) \left(\frac{d\theta}{2dr} \cos \frac{\theta}{2} \sin^2 \eta \phi + \frac{\eta}{r} \sin \frac{\theta}{2} \cos^2 \eta \phi \right) \right. \\ \left. - \left(\frac{d\theta}{2dr} \cos \frac{\theta}{2} \cos \eta \phi \sin \eta \phi - \frac{\eta}{r} \sin \frac{\theta}{2} \cos \phi \sin \eta \phi \right) \left(\frac{d\theta}{2dr} \cos \frac{\theta}{2} \cos \eta \phi \sin \eta \phi - \frac{\eta}{r} \sin \frac{\theta}{2} \cos \eta \phi \sin \eta \phi \right) \right\} \quad (123)$$

The terms which survive are

$$I_J = \eta \int d^2r \mathcal{M}(r) \frac{d\theta}{4rdr} \sin \theta = \frac{\pi\eta}{2} \int dr \mathcal{M}(r) \frac{d \cos \theta}{dr} \quad (124)$$

At $r = \infty$ $\cos \theta = 0$ and at $r = 0$ $\cos \theta = \pm 1$ according as the spin rotates parallel or antiparallel to the z axis.

Thus if \mathcal{M} is constant I_J is a topological invariant, proportional to the vorticity and to the sign of the rotation, but variation of the magnetization amplitude near the core means the amplitude is non-universal. In the extreme hard axis limit the spin remains in-plane over the whole region where $\mathcal{M} \neq 0$ and I_J vanishes. In general we can write

$$I_J = \eta \mathcal{C} \quad (125)$$

with \mathcal{C} of order 1 carrying the sign of the spin orientation in the vortex core and the magnitude factors associated with the variation of \mathcal{M} near the core.

Thus we finally obtain for the action

$$\begin{aligned} S = & i \int dt \sum_i T^* N^{xx} I_D \vec{X}_{Qi} \cdot \dot{\vec{X}}_{Qi} \\ & + \sum_i I_D \vec{X}_{Qi} \cdot \left(\vec{\mathcal{D}} - \mathcal{D}_0 \dot{\vec{X}}_{Ci} \right) \\ & + \vec{X}_{Qi} \cdot \left(\eta \mathcal{C} \hat{z} \times \left(\vec{\mathcal{J}} - \mathcal{J}_0 \dot{\vec{X}}_{Ci} \right) \right) \\ & - \sum_i \vec{X}_{Qi} \cdot \sum_j \frac{\partial U(\vec{X}_{C,i} - \vec{X}_{C,j})}{\partial \vec{X}_{C,i}} \end{aligned} \quad (126)$$

With the help of Eq. (108) we identify

$$\vec{F}_M = \eta \mathcal{C} \mathcal{J}_0 \hat{z} \times (\vec{u}_s - \dot{\vec{X}}) \quad (127)$$

as the Magnus force acting on a vortex. We see that it has a sign determined by the combination of the vorticity and the constant \mathcal{C} which describes the out of plane direction of spin rotation in the vortex core. Comparison to the usual theory of neutral superfluids (see e.g. Eq. (2.1) of Ref. 19) allows us to identify \mathcal{J}_0 with the combination $2\pi\rho_S/m$ (essentially 2π times the density of superfluid particles). On the other hand, to make contact with results obtained for superconductors it is more useful to identify $\vec{\mathcal{J}} = \mathcal{J}_0 \vec{u}_s$ with the supercurrent and to note that the combination $\mathcal{J}_0 \dot{\vec{X}}_C$ gives rise to the vortex Hall angle, which in superconductors is typically of order T_c/E_F and is in most cases negligible.

Proceeding similarly and using Eq. (110) we see that

$$\vec{F}_D = I_D \mathcal{D}_0 (\vec{u}_n - \dot{\vec{X}}) \quad (128)$$

represents the physics of dissipation. A very similar term occurs in superconductors and in the theory of neutral superfluid films (see e.g. Eq. (2.2) of Ref. 19), although in this case physics not relevant here produces an additional term proportional to $\hat{z} \times (\vec{u}_n - \dot{\vec{X}})$.

In neutral superfluids and superconductors, $\vec{u}_n - \dot{\vec{X}}$ represents the velocity of the vortex relative to the source of dissipation (the substrate, in the neutral superfluid case, or the normal-fluid excitations in a two-fluid model of the superconducting case). The relative magnitudes

of u_s and u_n is an important issue in the theory of superfluids shaken by motion of their container, but except perhaps in the ultra-clean limit u_n may be neglected in superconductors. However, in the magnetic case our estimates indicate that $u_s/u_n \sim \Gamma_{N-C}/\Gamma^{tot}$ is typically much less than unity.

The relative magnitudes of the dissipative ($I_D \mathcal{D}_0$) and non-dissipative (\mathcal{J}_0) terms sets the vortex Hall angle. In typical superconducting films the dissipative terms are dominant, but in the magnetic situation of relevance here the order of magnitude of the dissipative coefficient is set by the spin relaxation rate Γ_{N-C} which is likely to be small relative to the other terms in the vortex equation of motion.

For a single vortex (so $\vec{F}=0$) and in the absence of noise we may write the solution of Eq. (117) explicitly as

$$\begin{aligned} \frac{d\vec{X}}{dt} = & \left(\frac{\eta \mathcal{C} \mathcal{J}_0 I_D \mathcal{D}_0}{(I_D \mathcal{D}_0)^2 + (\eta \mathcal{C} \mathcal{J}_0)^2} \right) \hat{z} \times (\vec{u}_s - \vec{u}_n) \\ & - \left(\frac{(I_D \mathcal{D}_0)^2}{(I_D \mathcal{D}_0)^2 + (\eta \mathcal{C} \mathcal{J}_0)^2} \right) (\vec{u}_s - \vec{u}_n) + \vec{u}_s \end{aligned} \quad (129)$$

We observe that if either the spin relaxation rate (and hence \mathcal{D}_0) vanishes or if $\vec{u}_s = \vec{u}_n$, Eq. (129) implies, $\dot{\vec{X}} = \vec{u}_s$, so that the vortex simply drifts with the applied current. Thus in order to get motion transverse to current flow one needs both non-zero spin relaxation and a breaking of Galilean invariance $\vec{u}_s \neq \vec{u}_n$. In our model both of these effects arise from the presence of the spin reservoir.

Eq. (129) is very similar to the equation of motion for a vortex in a neutral superfluid given in Eq. (2.3) in Ref 19 which we rewrite below,

$$\begin{aligned} \frac{d\vec{R}}{dt} = & 2\pi n \hbar \rho_s^0 / m \left(\frac{B}{((2\pi \hbar / m) \rho_s^0 - B')^2 + B^2} \right) \hat{z} \times (\vec{v}_n - \vec{v}_s) \\ & + C (\vec{v}_n - \vec{v}_s) + \vec{v}_s \end{aligned} \quad (130)$$

Here \vec{v}_s is the superfluid velocity, while \vec{v}_n is the velocity of an underlying substrate which is also responsible for the dissipation and $n = \pm 1$ denotes the vorticity. B is a drag coefficient arising from coupling of the superfluid to the substrate, and B' is a drag coefficient arising from coupling of ripplon excitations to the curl of the superfluid velocity which does not appear in the case considered here. When $B' = 0$, the coefficient C defined in Ref. 19 equals $B^2 / ((2\pi \hbar / m) \rho_s^0)^2 + B^2$. Identifying B with $I_D \mathcal{D}_0$ and $(2\pi \hbar / m) \rho_s^0$ with $\mathcal{C} \mathcal{J}_0$ we see that the expressions become identical.

The important term for our subsequent considerations is the first one on the rhs of Eq. (129), which shows that vortices have a component of motion which is transverse to an applied current with sign determined by the combination $\eta \mathcal{C}$. The estimates presented in the previous section show that \mathcal{D}_0 is of the order of the ratio of the spin

relaxation rate Γ_{N-C} to the fermi energy E_F while \mathcal{D} is of the order of the ratio of the total scattering rate Γ^{tot} to the fermi energy. \mathcal{J}_0 is proportional to the magnetization while the spin current $\vec{\mathcal{J}}$ is proportional to m times the total current \vec{J} . Thus the transverse component X_T of vortex motion is roughly

$$\dot{X}_T \sim - \left(\eta \mathcal{C} \hat{z} \times \vec{J} \right) \frac{m I_D \frac{\Gamma^{tot}}{E_F}}{\left(I_D \frac{\Gamma_{N-C}}{E_F} \right)^2 + (\eta m \mathcal{C})^2} \quad (131)$$

Except very near to a magnetic transition or in the case of very strong spin relaxation the first term in the denominator is negligible and we have

$$\dot{X}_T \sim - \left(\eta \mathcal{C} \hat{z} \times \vec{J} \right) \left(\frac{I_D \Gamma^{tot}}{m \eta^2 \mathcal{C}^2} \right) \quad (132)$$

C. Interdefect Interaction

The force \mathcal{F}_{ij} between two vortices at positions X_i and X_j is given by

$$\mathcal{F}_{ij} = - \frac{\partial U(\vec{X}_{C,i} - \vec{X}_{C,j})}{\partial X_{C,i}^a} \quad (133)$$

It has contributions from the dipole force and from the usual spin stiffness terms. Writing $U = U_{SS} + U_{dip}$, the interaction arising from the spin stiffness is

$$U_{SS} = \frac{\pi \rho_S}{2} \ln \left| \frac{\vec{X}_{12}}{d} \right| \quad (134)$$

with ρ_S the spin stiffness per unit area.

In magnetic systems, unlike in superconductors, the dipole interaction may also be important. For a general spin configuration the dipolar energy may be written as

$$U_{dip} = (g \mu_B)^2 \int d^3 x d^3 x' \frac{\vec{\nabla} \cdot \vec{m}(x) \vec{\nabla} \cdot \vec{m}(x')}{|\vec{x} - \vec{x}'|} \quad (135)$$

with g the electron g-factor. Specializing to a two dimensional film of thickness d and considering the case of a vortex and an antivortex separated by the vector \vec{X}_{12} we obtain³⁰

$$U_{dip} = \eta_1 \eta_2 E_{dip} (\hat{X}_{12} \cdot \hat{m}) \frac{X_{12}}{d} \quad (136)$$

Here the dependence of X follows by power counting and $E_{dip} = (g \mu_B)^2 d^3 C_{dipole} (\hat{X}_{12} \cdot \hat{m})$ is the dipolar energy associated with magnetization in a volume set by the film thickness d , multiplied by a coefficient which depends on the relative orientation of the vortex/antivortex separation and the magnetization. We have evaluated the constant C_{dipole} numerically, finding $C_{dipole} \approx 110$ for a vortex/antivortex pair separated along the direction defined by the magnetization and $C_{dipole} \approx 35$ for a vortex/antivortex pair separated perpendicular to the direction defined by the magnetization.

VII. CURRENT-DRIVEN VORTEX UNBINDING TRANSITION

The previous section showed that vortices of opposite vorticity tend to be driven apart by an applied spin current but are pulled together by the intervortex force. The competition between these two effects leads to a current driven vortex unbinding transition. To investigate this possibility in more detail we consider the equation of motion of a single vortex-antivortex pair, obtained from the solutions of Eq. (117) for two vortices of opposite vorticity (more precisely opposite sign of $\eta \mathcal{C}$, and in what follows we take $|\eta| = 1$). We find that the equation for intervortex distance \vec{X}_{12} can be written

$$\dot{\vec{X}}_{12} = A \left(\vec{\mathcal{F}} - \vec{\mathcal{E}} \right) + \vec{\zeta} \quad (137)$$

with

$$A = \frac{2 I_D \mathcal{D}_0}{(I_D \mathcal{D}_0)^2 + (\mathcal{C} \mathcal{J}_0)^2} \quad (138)$$

The force term coupling the two vortices is given by Eq. (133). The current-induced force acting to separate the two vortices is

$$\vec{\mathcal{E}} = \mathcal{C} \hat{z} \times \left(\vec{\mathcal{J}} - \frac{\mathcal{J}_0}{\mathcal{D}_0} \vec{\mathcal{D}} \right) \quad (139)$$

We observe again that the net force vanishes if the Galilean-invariance condition $\mathcal{J}_0 \mathcal{D} = \mathcal{D}_0 \mathcal{J}$ is satisfied.

ζ is a noise field with correlations now given by

$$\langle \zeta_i^a(t) \zeta_j^b(t') \rangle = 2 A T_{eff} \delta_{ij} \delta^{ab} \delta(t - t') \quad (140)$$

with

$$T_{eff} = \frac{N^{xx} T^*}{\mathcal{D}_0} \quad (141)$$

Eqs. (137), (136) show that if the applied current is large enough that

$$\delta \mathcal{E} = \frac{\mathcal{C}}{\mathcal{D}_0} (-\mathcal{J}_0 \mathcal{D} + \mathcal{D}_0 \mathcal{J}) - \frac{E_{dip}}{d} > 0 \quad (142)$$

then at sufficiently long distances it becomes energetically favorable to separate vortex/antivortex pairs.

To calculate the probability of formation of vortex/antivortex pairs we follow Ref. 19 and recast Eq. (137) as a Fokker-Planck equation for the probability P per unit area of finding a vortex-antivortex pair at separation r :

$$\partial_t P(\vec{r}, t) = - \vec{\nabla} \cdot \vec{J}_P \quad (143)$$

Here, the probability current J_P is given by

$$\vec{J}_P = - A T_{eff} e^{-\frac{\vec{v}}{T_{eff}}} \vec{\nabla} P(\vec{r}, t) e^{\frac{\vec{v}}{T_{eff}}} \quad (144)$$

and effective potential

$$\bar{U} = \left[E_{dip} \frac{|\vec{r}|}{d} + \frac{\pi \rho_S}{2} \ln \frac{|\vec{r}|}{d} \right] - \mathcal{E} \hat{x} \cdot \vec{r} \quad (145)$$

In the limit of relatively weak applied currents, Eq. (143) may be analyzed by saddle-point method.^{19,31} We take the electrical current to be applied in the y direction, so the vortex/antivortex pair separates along x and choose $x = y = 0$ as the location of the saddle point in \bar{U} with $x \rightarrow \infty$ corresponding to large vortex/antivortex separation. We assume that the probability current density is only large near the saddle point of \bar{U} and seek a steady-state solution with $J_P^y = 0$. The pair creation rate per unit area R is then given in terms of the y integral of the x component of the probability current as^{19,31}

$$R = \int dy J_P^x(x=0, y) \quad (146)$$

To determine R we observe that the condition that $J_P^y = 0$ is fulfilled if P has a y dependence which compensates the y dependence of \bar{U} , i.e.

$$P(\vec{r}, t) e^{\frac{\bar{U}}{T_{eff}}} = f(x, t) \quad (147)$$

For $x \rightarrow \infty$ the density of vortex/antivortex pairs is very low, so $f \rightarrow 0$, whereas for intervortex separations much less than the saddle point value we expect the probability distribution to be the pseudoequilibrium one corresponding to temperature T_{eff} so $f(x \ll 0) \rightarrow 1$. The steady state condition is fulfilled if J_P^x depends only on y , i.e.

$$J_P^x = \Phi(y) = -AT_{eff} e^{-\frac{\bar{U}}{T_{eff}}} \partial_x f(x) \quad (148)$$

Multiplying both sides of Eq. (148) by $e^{-\frac{\bar{U}}{T_{eff}}}$, integrating over x using the boundary conditions on f and rearranging then gives

$$\Phi(y) = \frac{AT_{eff}}{\int_{x_{low}}^{\infty} dx' e^{\frac{\bar{U}(x', y)}{T_{eff}}}} \quad (149)$$

with x_{low} sufficient far from the saddle point that $f \approx 1$.

To implement these formulae we now make the saddle point approximation explicit. The saddle point location r_c is

$$\vec{r}_c = \left(\frac{\pi \rho_S}{2\delta\mathcal{E}}, 0 \right) \quad (150)$$

Near the saddle point we write

$$\frac{\bar{U}(\delta x, \delta y)}{T_{eff}} = \bar{u} + \frac{\delta y^2}{2y_c^2} - \frac{\delta x^2}{2x_c^2} \quad (151)$$

with

$$\bar{u} = \frac{\pi \rho_S}{2T_{eff}} \ln \frac{r_c}{d} - \frac{\pi \rho_S}{2T_{eff}} \quad (152)$$

$$y_c^{-2} = \frac{E_{dip}}{T_{eff} d r_c} + \frac{\pi \rho_S}{2T_{eff} r_c^2} \quad (153)$$

$$x_c^{-2} = \frac{\pi \rho_S}{2T_{eff} r_c^2} \quad (154)$$

Thus Eq. (148) becomes

$$J_P^x(y) = \frac{AT_{eff}}{x_c \sqrt{2\pi}} e^{-\bar{u}} e^{-\frac{y^2}{2y_c^2}} \quad (155)$$

so, performing the y integral and restoring units

$$R = \frac{2I_D N^{xx} T^*}{(I_D \mathcal{D}_0)^2 + (\mathcal{C} \mathcal{J}_0)^2} \frac{1}{\sqrt{1 + \frac{E_{dip}}{d \delta \mathcal{E}}}} \left(\frac{2e \delta \mathcal{E} d}{\pi \rho_S} \right)^{\mathcal{D}_0 \frac{\pi \rho_S}{2N^{xx} T^*}} \quad (156)$$

Because the vortex annihilation rate scales as the square of the vortex density and must balance the creation rate, we obtain

$$n_V \sim \left(\frac{2\delta \mathcal{E} d}{\pi \rho_S} \right)^{\mathcal{D}_0 \frac{\pi \rho_S}{4N^{xx} T^*}} \quad (157)$$

VIII. CONCLUSIONS

In this paper we have shown that an applied current can drive a nonequilibrium topological (defect-unbinding) transition in a continuous-symmetry magnet. We derived the appropriate action from microscopics and presented specific results for a quasi two-dimensional XY symmetry magnet, providing estimates for the relevant length and current scales and characterizing the scaling of defect density as the current exceeds threshold. A qualitative result is that, in the presence of the dipole interaction, the critical current depends strongly (by a factor of ~ 3) on the angle between the current and the magnetization. Our general formalism and qualitative conclusions however apply to any combination of dimensionality and order parameter structure which supports topological defects. These results complement the treatment of current-driven quantum criticality studied in Refs. 1,13 which considered transitions dominated by current-induced local spin excitations in Ising and Heisenberg magnets.

The basic physics driving the transition, namely that an applied current produces a force which acts oppositely on vortices of different chirality, is familiar from the theory of vortices in superconductivity^{19,20} and has been derived^{17,18,29} from the Landau-Lifshitz-Gilbert equations which provide a phenomenological description of magnetization dynamics in the presence of applied currents. We note here that the relevant quantity for vortices is the combination of the chirality and the index giving the spin direction in the vortex core.

The new contributions of the present paper include a derivation of the Landau-Lifshitz-Gilbert equations from microscopics which is based on a theory of the rotational degrees of freedom, complementing previous derivations.^{21,23,25} We have also included the magnetic dipole energy, which is found to make a numerically large contribution. The fact that the dipole interaction couples spin and space directions leads to the dependence of

critical current on angle between current and magnetization. We have distinguished the transport and spin relaxation scattering processes, derived an expression (following Ref. 13) for the current-induced quasithermal noise, and explicated in detail the correspondence between superconducting and magnetic vortices. The most important difference is that in the magnetic case dissipative effects are in general expected to be weak so the vortex Hall angle is generically close to $\pi/2$.

An important question concerns the experimental observability of the transition we discuss. Current-induced vortex motion has been observed.^{32–35} The relative magnitude of the adiabatic and non-adiabatic spin transfer torques has been determined by studying displacement of vortices in permalloy discs.³⁴ In Ref 32 the nucleation and annihilation of magnetic vortices due to current induced spin transfer torque, an effect which has been theoretically predicted,^{17,18} was observed in NiFe wires. Jonietz *et al* used neutron scattering to detect a current-induced shift in the skyrmion lattice in the helimagnet *MnSi*. It was theoretically shown in Ref 36, and later experimentally confirmed³³ that moving vortices can produce a “ferro”-Josephson effect where a voltage drop can be

induced in the direction transverse to the motion of a vortex. The current induced vortex binding unbinding transition discussed in this paper should create a similar additional voltage drop arising from the motion of free vortices. Thus the effects we predict are in principle observable.

A crucial simplifying assumption made in this paper was that the vortex-induced length scales are long enough that we may assume that the quasi-particle distribution relaxes to a steady state determined by the local magnetization. It is quite likely that in many cases this locality assumption is violated, and that issues arise analogous to those arising in the physics of vortex motion in clean superconductors. Investigating this issue is an important direction for future research. Further important open questions concern the nucleation of vortices at sample boundaries, magnetic domain walls, and near local inhomogeneities, and also the extension of our work to other cases such as monopoles in three dimensional magnets.
